

Neural Networks for Sequence Data

CMPUT 261: Introduction to Artificial Intelligence

GBC §10.0-10.2
P §12.1-12.2, §12.4, §12.6

Lecture Outline

1. Midterm Review
2. Recap & Logistics
3. Unfolding Computations
4. Recurrent Neural Networks
5. Attention & Transformers

After this lecture, you should be able to:

- demonstrate unfolding a recurrent expression
- explain the problems with handling sequence input using dense or convolutional neural networks
- explain the high-level idea behind neural networks and transformers
- describe how self-attention combines inputs to generate its outputs
- describe the architecture of a transformer layer
- explain the high-level idea behind encoder-decoder architectures

Midterm Review: Admissible Heuristic

Consider the following heuristic function:

$$h(s) = \sum_{\text{positions } y} 1[\text{switch at position } y \text{ is off}]d(\text{pos}(s), y).$$

Is the heuristic function h an *admissible heuristic* for this problem? Why or why not?

- Heuristic adds up cost to get from current position to position y for every position y
- But that's more actions than you need to take for *any* solution
- **Question:** What will h return from a state where all the switches are in the **off** state and SwitchBot is in position **G**?
- **Question:** Can an admissible heuristic ever **dominate** a non-admissible heuristic?

Midterm Review: Short Answer

- Which of breadth-first search, least-cost-first search, and A^* search has the best **worst-case** time complexity? Why?
- Why is loss on the **test set** a good estimator for generalization error?

Logistics: Assignment #3

- **Assignment 3** is due **Tuesday Nov 21** at 11:59pm
 - Late submissions until the following Friday with 20% deduction
- Next week is **reading week**
 - No labs or lectures
- **Midterm** marks are available on eclass

Recap:

Convolutional Neural Networks

- Convolutional networks: Specialized architecture for **images**
- Number of **parameters** controlled by using **convolutions** and **pooling** operations instead of **dense connections**
- Fewer parameters means more **efficient to train**

(Images: Goodfellow 2016)

Sequence Modelling

- For many tasks, especially involving language, we want to model the behaviour of **sequences**
- **Example:** Translation
 - The cat is on the carpet $\Rightarrow$ Le chat est sur le tapis
- **Example:** Sentiment analysis
 - This pie is great $\Rightarrow$ POSITIVE
 - This pie is okay, not great $\Rightarrow$ NEUTRAL
 - This pie is not okay $\Rightarrow$ NEGATIVE

Sequential Inputs

The cat is on the carpet

Question: How should we **represent** sequential input to a neural network?

1. 1-hot vector for **each word**
(Sequence must be a specific length?)
2. 1-hot vector for **last few words**
(n -gram)
3. **Single vector** indicating each word that is present
(bag of words)

One-Hot Representations

carpet

One-hot representations of words have some problems:

1. **Wasteful:** Each input vector must have a dimension equal to the size of the vocabulary (possible words)
 - If vocabulary has 30,000 words, then each vector has 29,999 zeros
2. **Poor generalization:** Ideally, similar words would be treated similarly
 - Exploiting meaningful similarity between images was an important feature of convolutional neural networks

[illegible]

Semantic Embeddings

- The usual approach is to first learn a **semantic embedding** for one-hot vectors
- Every word gets represented as a **dense vector** with smaller dimension than the vocabulary (typical size: 1,024)
- **Goal:** Words with similar **meanings** will have small **distance** between embedded vectors; words with different meanings will have large **distance** between embedded vectors

(Pre-)Training Semantic Embeddings

Question: How many **parameters** are required to convert a one-hot encoding for vocabulary of V words into a D -dimensional embedding?

- Embeddings require the training of **many** parameters
- Fortunately, this can be done with **unlabeled** data
- **Trick:** "Pre-train" neural network for a task that we don't care about
 - But which can be evaluated using unlabeled data
 - Predicting words from k nearby words
 - Predicting "masked" words
- Keep the weights that convert the one-hot layer into a dense embedding layer
- Throw away the weights that convert the embedding layer into output

Processing Variable-Length Sequences

- Image inputs can be restricted to a **standard size** (20x20, 1024x768, etc.)
- Sequence inputs (e.g., text) are **variable-length**
 - And often **very long**
- **Solution:** Apply the **same operations** to each position in the sequence
- Two such approaches:
 1. **Recurrent neural networks:**
input is current token + fixed-dimension "state" from previous operation
 2. **Transformers / self-attention:** Size of state varies with size of sequence

Dynamical Systems

- A **dynamical system** is a system whose state at time $t + 1$ depends on its state at time t :

$$\mathbf{s}^{(t)} = f(\mathbf{s}^{(t-1)}; \theta)$$

- An expression that depends on the same expression at an earlier time is **recurrent**.

Unfolding Computations

- A recurrent expression can be converted to a non-recurrent expression by **unfolding**:

$$\begin{aligned}\mathbf{s}^{(3)} &= f(\mathbf{s}^{(2)}; \theta) \\ &= f(f(\mathbf{s}^{(1)}; \theta); \theta)\end{aligned}$$

External Signals

- Dynamical systems can also be driven by **external signals**:

$$\mathbf{s}^{(t)} = f(\mathbf{s}^{(t-1)}, \mathbf{x}^{(t)}; \theta)$$

- These systems can also be represented by non-recurrent, unfolded computations:

Recurrent Neural Networks

- Recurrent neural network: a specialized architecture for modelling **sequential data**
- Input presented **one element at a time**
- Parameter sharing by:
 - Treating the sequence as a system with **state**
 - Introducing hidden layers that **represent** state
 - Computing **state transitions** and **output** using **same functions** at each stage
- The **same computation** is applied to each pair of state and input
 - But the state is different after each application

$$\mathbf{x}^{(6)} = \begin{matrix} \text{carpet} & \bullet \\ & \circ \\ & \circ \\ & \circ \end{matrix}$$

Recurrent Hidden Units: Sequence to Sequence

- **Input values x** connected to **hidden state h** by weights U
- Hidden state h mapped to **output o** by weights V
- Hidden state $h^{(t-1)}$ connected to hidden state $h^{(t)}$ by weights W
- Gradients computed by **back propagation through time**: from final loss all the way back to initial input.
- All hidden states computed must be **stored** for computing gradients

Recurrent Hidden Units: Sequence to Single Output

- Update state as inputs are provided
- Only compute a **single** output at the **end**
- **W**, **U** still shared at every stage
- Back propagation through time still requires **evaluating every state** in gradient computation

Encoder/Decoder Architecture for Sequence to Sequence

Can **combine approaches** for sequence-to-sequence:

1. Accept entire input to construct a single "**context**" output **C**
2. Construct new sequence using context **C** as **only input**

Long-Range Dependence

The **submarine**, which was the subject of a well known song by the Beatles, was **yellow**.

- Information sometimes needs to be **accumulated** for a long part of the sequence
- But **how long** an individual piece of information should be accumulated is **context-dependent**
- Long-range dependence can be difficult for a recurrent network
- Often need to **accumulate** information in the state, and then **forget** it later

Self-Attention vs. RNN

- **RNN:** accept "previous" state and current input; output "next" state
 - Final output is last state
- **Self-attention:** Accept ALL inputs
 - Final output is ALL states

Self-Attention

- Each input is transformed into a single output
 - N inputs means N outputs
- An output is computed by:
 1. Each **input** x_i transformed into **value** v_i by a **linear** operation

$$v_i = \beta_v + \Omega x_i$$

2. Each **output** y_j is a **weighted combination** of the **values**:

$$y_j = \sum_i a[x_i, x_j] v_i$$

Dot-Product Self-Attention

- A **self-attention unit** computes **three values** for each input x_i :
 - Query** q_i , **Key** k_i , and **Value** v_i
 - These values are computed in the **same way** for each input

- Each output is a **weighted** combination of the **values** of **all** inputs:

$$y_j = \sum_i a[x_i, x_j] v_i = \sum_i w_{ij} v_i$$

- Weight for output y_j of **value** x_i is proportional to the dot-product of j 's **query** and i 's **key**

$$w_{ij} = \frac{\exp(q_j^\top k_i)}{\sum_\ell \exp(q_j^\top k_\ell)}$$

Transformer Blocks

- A **transformer layer** is a **self-attention** unit followed by a **dense feedforward network**
- The **same** feedforward network gets applied to each output of the self-attention unit:

$$y_j = \text{mlp}(x_j; \Omega) \quad \text{for } j = 1, \dots, N$$

- In a typical transformer architecture, several transformer blocks will be strung together in parallel ("multiple heads")

Training a Transformer Network (for encoding tasks)

Transformers are trained in two phases:

1. **Semi-supervised pre-training:** Using a very large dataset, train the network to perform task for which dataset implies the answer

- we **need not label** the examples manually
- e.g., predicting masked words

Question: Is this important? Why?

2. **Fully supervised fine-tuning:**

Add another layer or two at the end, and train for the real task using manually labelled examples

- e.g., sentiment analysis, word classification, text span prediction

Pre-training

- Subset of tokens in an example sequence are **masked** (replaced with a special token)
- Neural network applied to each masked output predicts probabilities for missing token
 - Loss is back-propagated through entire network
- At end of training, that neural network is **thrown away**

(Image: Prince 2022)

Fine-tuning: BERT for Sentiment classification

- **Sentiment classification:** Predict if a sequence is positive or negative
- First token of sequence is always a special "classify" token
- Neural network trained on corresponding output token using labelled dataset

Summary

- Naively representing **sequential inputs** for a neural network requires infeasibly many input nodes (and hence **parameters**)
- One-hot encodings are wastefully large and have no semantic structure
 - **Embeddings** solve these problems and can be trained without explicit labels
- **Recurrent neural networks** are a **specialized architecture** for sequential inputs
 - **State** accumulates across input elements
 - Each stage computed from **previous stage** using **same parameters**
- **Transformers** are another specialized architecture!
 - **Self-attention** to combine inputs instead of accumulating state
 - All states output (not just last in a sequence)
 - Improved ability to attend to long-range dependence
 - Admits of better parallel evaluation
 - Pre-training followed by fine-tuning
 - Classification: attend to the output corresponding to a special "classify" input token
